# Inter-pregnancy weight change impacts placental weight and is associated with the risk of adverse pregnancy outcomes in the second pregnancy

Jacqueline M Wallace<sup>1\*</sup>, Sohinee Bhattacharya<sup>2</sup>, Doris M Campbell<sup>2</sup> and Graham W Horgan<sup>3</sup>

## Abstract

**Background:** The inter-pregnancy period is considered a teachable moment when women are receptive to weight- management guidance aimed at optimising pregnancy outcome in subsequent pregnancies. In population based studies inter-pregnancy weight change is associated with several adverse pregnancy outcomes but the impact on placental size is unknown.

**Methods:** The association between inter-pregnancy weight change and the primary risk of adverse pregnancy outcomes in the second pregnancy was investigated in 12,740 women with first two consecutive deliveries at a single hospital using logistic regression.

**Results:** Compared with women who were weight stable, weight loss (>1BMI unit) between pregnancies was associated with an increased risk of spontaneous preterm delivery, low placental weight and small for gestational age (SGA) birth, while weight gain (>3BMI units) increased the risk of pre-eclampsia, gestational hypertension, emergency caesarean section, placental oversize and large for gestational age (LGA) birth at the second pregnancy. The relationship between weight gain and pre-eclampsia risk was evident in women who were overweight at first pregnancy only (BMI  $\geq 25$  units), while that between weight loss and preterm delivery was confined to women with a healthy weight at first pregnancy (BMI <25 units). In contrast, the association between weight loss and SGA was independent of first pregnancy BMI. A higher percentage of women who were obese at first pregnancy were likely to experience a large weight gain ( $P < 0.01$ ) or weight loss ( $P < 0.001$ ) between consecutive pregnancies compared with the normal BMI reference group.

**Conclusion:** Inter-pregnancy weight change in either direction increases the risk of a number of contrasting pregnancy complications, including extremes of placental weight. The placenta may lie on the causal pathway between BMI change and the risk of LGA or SGA birth.

## Background

Both pre-pregnancy maternal underweight and obesity are associated with a myriad of adverse pregnancy outcomes for both mother and child, which impact their health and wellbeing, and draw substantially on limited health service resources [1-3]. Women who are underweight at conception are at risk of fetal growth restriction, premature

delivery and low birth weight [4-7]. At the other end of the BMI spectrum, maternal obesity is commonly associated with a plethora of risks that generally increase with degree of overweight including hypertensive disorders, gestational diabetes, stillbirth, induction of labour, caesarean delivery, large for gestational age (LGA, birth weight >90<sup>th</sup> after adjustment for gender and gestational age) and preterm birth [4,8-11]. Avoiding the consequences of these BMI extremes by encouraging women to achieve a healthy BMI prior to their first pregnancy is a laudable goal but it is pertinent to recognise that many of these pregnancies are largely

unplanned. This is particularly true for younger and socially deprived women who predominate in the underweight and obese BMI categories, respectively [12-14]. The inter-pregnancy period may be a “teachable moment” when women are receptive to guidance to achieve or maintain a healthy weight and thereby optimise pregnancy outcome in their second pregnancy. This guidance must be evidence based and applicable to all women across the BMI range. Previous population based studies from Sweden and the USA (~114-230,000 women) have examined inter-pregnancy BMI changes in relation to a number of pregnancy complications [15-22]. Using contrasting approaches these researchers have demonstrated a strong relationship between inter-pregnancy weight gain and the risk of pre-eclampsia, stillbirth, maternal diabetes, LGA and caesarean delivery. Villamer & Cnattingius [15] additionally detected a linear relationship between inter-pregnancy weight gain and the incidence of gestational hypertension while Whiteman et al. [22] reported that inter-pregnancy BMI loss resulting in a shift from the normal to underweight category increased the risk of spontaneous preterm delivery. The effect of inter-pregnancy BMI change on the primary incidence of small for gestation age (SGA) has not been documented.

We recently demonstrated that placental growth as reflected by weight at delivery is an independent risk factor for the range of pregnancy complications shown to be influenced by the contrasting ends of the BMI spectrum in the pregnant population irrespective of parity [23]. Inter-pregnancy BMI change may also influence placental weight at the second pregnancy and hence hypothetically the placenta may lie in the causative pathway between BMI change and the risk of specific adverse pregnancy outcomes. The aims herein were three-fold. Firstly we aimed to determine if both extremes of inter-pregnancy weight change influenced the risk of a range of pregnancy outcomes, including SGA births, in a relatively small cohort of women delivering at a single maternity unit in the UK. We deliberately used the same analytical approach as Villamer and Cnattingius [15] to facilitate comparison of common elements of our data. Secondly we examined whether the relationships between inter-pregnancy weight change and the primary incidence of pregnancy complications at second pregnancy differed in women who had a healthy or unhealthy BMI at the first pregnancy. Thirdly, we investigated whether inter-pregnancy BMI change influenced the incidence of low placental weight (<10<sup>th</sup> centile after adjustment for gender and gestational age) or placental oversize (>90<sup>th</sup> centile after adjustment) at the second pregnancy.

## Methods

### Study population

This was a retrospective cohort study using data from the Aberdeen Maternity and Neonatal Databank (AMND).

Ethical approval was granted by the North of Scotland Research Ethics Service (REC Ref 13/NS/0050) for all observational studies using routinely collected anonymised data from the AMND, provided permission was granted by the Steering Committee (Caldicott guardians). After obtaining permission from the Steering Committee of the AMND, routinely collected anonymised data were extracted from the databank for all singleton births after 24 weeks' gestation in Aberdeen city and district between 1986 and 2007. The study population of interest was women who had their first-ever and second consecutive births at Aberdeen Maternity Hospital, who booked before 24 weeks gestation on both occasions and whose height and weight was recorded. After excluding women (n = 955) with missing or improbable data for key variables (placental weight, birth weight or baby gender), a final study population of 12,740 women were available for analysis.

### Study design

Maternal weight at the first antenatal visit for each pregnancy was adjusted to take into account stage of gestation when weight was measured exactly as described previously using maternal conformation data for women from the same geographical area [24]. Briefly this involved obtaining the z score of weight for height (difference between weight and mean weight for height, relative to standard deviation), adjusting this by adding a constant that depended on stage of gestation, and then recalculating a weight only from this adjusted z score. The resulting corrected weight was then used together with the unadjusted height to calculate an adjusted BMI (weight/height<sup>2</sup>). Although the mean individual difference in gestational age at the initial hospital visit in the first versus second pregnancy was small (1 ± 3 weeks, mean ± SD) this approach meant that the maternal BMI calculated for both pregnancies was corrected to a standard stage of gestation for all women in the study population. Moreover as a small percentage of women had their first hospital visit after 16 weeks gestation (13 and 7% of women in first and second pregnancies, respectively) this approach facilitated the inclusion of women who had a first hospital booking appointment up to 23 weeks gestation. These adjusted maternal BMIs were used to calculate the inter-pregnancy change in BMI. The difference was categorised as less than -1 (BMI loss of greater than 1 unit), -1 to less than 1 (BMI stable = reference group), 1 to less than 3 (modest gain) and 3 or more units (large gain) and replicate the BMI categories used in the Scandinavian population based study reported by Villamor and Cnattingius (15). Initial BMI at the beginning of the first pregnancy was categorised using conventional cut-off points for underweight (<18.5), normal weight (18.5-24.9), overweight (25.0-29.9) or obese (≥30). Other covariates including maternal age, height, year of delivery and smoking habit were grouped as detailed in

Table 1. The inter-delivery interval was calculated in years between the birth of the first and second child.

The pregnancy complications and obstetric outcomes assessed included pre-eclampsia and gestational hypertension (coded according to the ISSHP definition, [25]), placental abruption, placenta praevia, postpartum haemorrhage (defined as blood loss of more than 500 ml or 1000 ml at vaginal or Caesarean delivery respectively), type of labour (spontaneous or induced), type of delivery (spontaneous vaginal, instrumental, elective or emergency Caesarean section), spontaneous preterm delivery (<37 weeks) and post-term delivery (>41 weeks). Gestational age was recorded according to the last menstrual period and was confirmed by ultrasound. Where there was disagreement of more than 7 days, the ultrasound date was taken as the actual gestational age. Perinatal outcomes included stillbirth, birth weight and placental weight. The latter was weighed untrimmed and recorded to the nearest 10 g. Birth weight was defined as small for gestational age (SGA) if weight was less than the 10<sup>th</sup> centile or large for gestational age (LGA) if weight was above the 90<sup>th</sup> centile for gestation using gender and parity specific birth weight charts for Scottish singleton births [26]. Similarly gestational age, gender and parity grouping specific placental weight charts were used to define low placental weight (<10<sup>th</sup> centile) and placental oversize (>90<sup>th</sup> centile). These were derived from the AMND [27].

### Statistical analysis

In Table 1 the frequency of maternal characteristics and outcomes of first pregnancy in relation to the BMI change category between pregnancies was analysed by Chi-Square tests. In addition the distribution of inter-pregnancy weight (BMI) change as a continuous variable was compared with maternal characteristics and outcomes of the first pregnancy as categorical predictors using one-way ANOVA. The effect of initial BMI category at first pregnancy and direction of BMI change category between pregnancies on inter-pregnancy BMI change was analysed using ANOVA (Linear Model) and differences between BMI groups were compared by Tukey's method (data in text). The significance of any trend in the incidence rate of each pregnancy complication in the second pregnancy in relation to the BMI change since the first pregnancy (Table 2) was evaluated by the Cochran-Armitage test for (a) women who experienced the specific complication in the second pregnancy only and (b) for all women irrespective of first pregnancy history. The latter may be of value in estimating trends and risk in situations where the first pregnancy complications have not been clinically documented. The risk of pregnancy complications in the second pregnancy in relation to inter-pregnancy BMI change were assessed using logistic regression (Table 2). Risks are

presented as Odds Ratios (OR) with 95% confidence intervals (CI) and were adjusted for BMI at first pregnancy, height, inter-delivery interval, along with maternal age and smoking status, year of delivery, baby gender and gestational age at second pregnancy. Where appropriate, variables were additionally adjusted for the co-occurrence of either pre-eclampsia or gestational hypertension. After testing for an interaction between BMI category at baseline and BMI change category, we further investigated whether BMI at the beginning of the first pregnancy modified any relationship between inter-pregnancy BMI change and pregnancy complication risk at the second pregnancy by repeating the above logistic regression approach for women who had a BMI below or above 25 at the first pregnancy (Table 3).

The Cochran-Armitage test was carried out using R (Foundation for Statistical Computing, Vienna, Austria) and all other statistical analysis was carried out using Minitab (version 15; Minitab Inc., State College, PA).

## Results

### Pregnancy complications and baseline BMI

Maternal and pregnancy outcome characteristics at the first and second pregnancy in relation to BMI category at first pregnancy are detailed (Additional file 1). At the first baseline pregnancy 2% of women were underweight, 63% were normal weight, 26% were overweight and 9% were obese and there was no major difference in inter-delivery interval between groups.

### Pregnancy complications and inter-pregnancy change in BMI

On average women gained one BMI unit (median 0.7, IQR -0.3 to 2.0) during a mean pregnancy interval of 3.4 years (median 3.0, IQR 2 to 4). Table 1 details the frequency of maternal characteristics and outcomes of the first pregnancy in relation to the BMI change category between pregnancies. It also details the average change in BMI between the first and second pregnancy in relation to these parameters. The number of women per BMI change category was influenced by age, height, first pregnancy BMI, smoking habit and inter-delivery interval and hence all these parameters were adjusted for in the logistic regression analysis. Similarly, the incidence of pre-eclampsia, gestational hypertension, induced and instrumental deliveries, placental abruption, LGA and extremes of placental weight at the first pregnancy varied by BMI change category. Irrespective of BMI change category, on average, weight gain between the first and second pregnancy was not influenced by smoking habit, decreased with age and height, and increased with the inter-delivery interval. Weight gain between the first and second pregnancy was greater in women who had gestational hypertension, induced labour, LGA and placental weight > 90<sup>th</sup> centile, and lower in women with a

\*Values are percentage of women. \*P values obtained from a chi-squared test of counts.

low placental weight in the first pregnancy. The groups of women classified as underweight or obese at baseline had the largest change in average weight between pregnancies (Table 1) and the direction of weight/BMI change is presented in more detail in Figure 1. Of the group of women who were underweight at baseline, few subsequently lost weight and more gained a modest amount of weight compared with all other baseline BMI categories ( $P < 0.01$ ). While fewer women who were obese at baseline were weight stable or gained a modest amount of weight, more gained a large amount of weight between pregnancies than all other categories ( $P < 0.01$ ). Counter-intuitively, more initially overweight or obese women also lost weight between pregnancies than in the normal weight stable reference group ( $P < 0.001$ ). In the relatively weight stable and modest gain groups the extent of individual weight change was independent of initial BMI category. In contrast the extent of inter-pregnancy weight change in the loss group was linearly associated with initial BMI category (equivalent to an average of -1.4, -1.6, -2.1 and -3.0 BMI units for underweight, normal, overweight and obese groups, respectively) and was statistically higher in women initially categorized as obese relative to all other groups ( $P < 0.001$ ). Similarly for women with a large inter-pregnancy gain in BMI (equivalent to an average of 5.0, 4.7, 5.1 and 5.3 BMI units for underweight, normal, overweight and obese groups, respectively), the gain was highest in the overweight and obese compared with the normal reference group ( $P < 0.001$ ).

In Table 2 incidence rate and adjusted odds ratios for adverse perinatal outcomes during the second

pregnancy, in relation to BMI change category between the first and second pregnancy, are presented for women experiencing the individual complication in the second pregnancy only and for all women irrespective of previous history. In both cases data are shown for those adverse outcomes where weight change was associated with statistically significant linear trends across the BMI change spectrum and/or adjusted odds ratios only (non-significant adjusted odds ratios for the remaining pregnancy complications and unadjusted odds ratios for all pregnancy complications for women experiencing the complication in the second pregnancy only are available in Additional file 2). For women experiencing a complication in the second pregnancy only (Table 2a), a weight gain equivalent to more than 3 BMI units (median 4.3, IQR 3.5 to 5.7) was associated with an increased risk of pre-eclampsia, gestational hypertension, emergency caesarean section and LGA (OR 1.59 to 1.85) and was protective against spontaneous preterm labour (OR 0.65). In contrast women who lost more than 1 BMI unit (median -1.6, IQR -2.3 to -1.3) had a higher risk of induced labour, spontaneous preterm delivery and SGA (OR 1.21 to 1.67) and a lower risk of LGA (OR 0.57) relative to the stable BMI reference group (median 0.1, IQR -0.3 to 0.5). The size and direction of the associations between inter-pregnancy weight change and most pregnancy complications was similar for all women irrespective of first pregnancy history (Table 2b). The exception was the risk of induced labour which was slightly higher in both weight gain categories when all women were included.

**Table 2 Frequency rate and adjusted odds ratios for adverse perinatal outcomes during second pregnancy in relation to change in BMI from first pregnancy (a) for women with specific complication in second pregnancy only and (b) for all women irrespective of first pregnancy history**

### Pregnancy complications, baseline BMI category and inter-pregnancy change in BMI

When the putative interaction between baseline BMI category and inter-pregnancy change in BMI category were examined, statistically significant interactions (weight change effects differing between the four baseline BMI categories) were evident for the risk of some of the most prevalent adverse pregnancy outcomes, namely emergency caesarean section (P = 0.012), LGA (P = 0.009) and placental weight >90<sup>th</sup> centile (P = 0.004). On this basis and cognizant that this initial approach may miss detecting interactions for less prevalent outcomes we further subdivided the data and compared the effects of weight change between pregnancies on second pregnancy primary complication risk for women who had a BMI less than 25 (median 22.4, IQR 21.0 to 23.6) with those who had a BMI above 25 (median 27.5, IQR 26.0 to 30.0) at first pregnancy. This equated to 65 versus 35% of the study population, respectively (Table 3). Data are shown for those adverse outcomes where weight change was associated with significant linear trends across the BMI change spectrum and/or adjusted odds ratios in at least one baseline BMI category. Women who were overweight at baseline and who had a modest (median 1.9, IQR 1.4 to 2.4) or large (median 4.5, IQR 3.7 to 6.0) gain in BMI between pregnancies had a two and three fold higher risk of pre-eclampsia at the second pregnancy compared with overweight women who were BMI stable (median 0.1, IQR -0.4 to 0.5). No such relationship was evident in women with baseline BMI less than 25 units (healthy weight). In contrast an 80% greater risk of spontaneous pre-term labour was evident in women who lost weight between pregnancies and who had a baseline BMI less than 25 units but not in women who were overweight at baseline. Similarly, both inter-pregnancy weight loss and weight gain heightened the risk of requiring an emergency section in women who had a baseline BMI less than 25 only, with the highest overall risk in the largest BMI gain category. The direction of the association between weight change and the remaining adverse outcomes shown, namely gestational hypertension and both birth weight extremes was

similar in both baseline BMI categories but significantly stronger in women whose BMI was less than 25 at the outset. There was no effect of inter-pregnancy weight change on the crude or adjusted risk of stillbirth, post-term delivery, postpartum haemorrhage, placental abruption or placenta praevia (see Additional file 2) in the population overall and when examined in relation to baseline BMI category.

### Inter-pregnancy BMI change and placental weight

Average placental weight increased by 36 g between the first (median 600, IQR 520 to 700 g) and second pregnancy (median 630, IQR 550 to 725 g, P < 0.001). The difference in placental weight at delivery in successive pregnancies after adjustment for inter-delivery interval and maternal height along with age, gestation length and smoking status in both pregnancies was -0.4, 17.4, 24.1 and 30.2 g for women in the weight loss, weight stable, modest and large weight gain categories, respectively (P < 0.001). In the second pregnancy, inter-pregnancy BMI change, through the BMI loss to large gain categories was inversely related to the incidence of low placental weight (<10<sup>th</sup> centile) and positively related to the incidence of high placental weight (>90<sup>th</sup> centile) in the population as a whole (Table 2), and in women who were either overweight or had a relatively healthy weight at baseline (Table 3). Thus for the population overall, women who lost weight between pregnancies (13%) were more likely to have a very small placenta (OR 1.67) while women who gained a modest (29%) or large amount of weight (14%) were more likely to have a large placenta (OR 1.26 and 1.59, respectively).

### Discussion

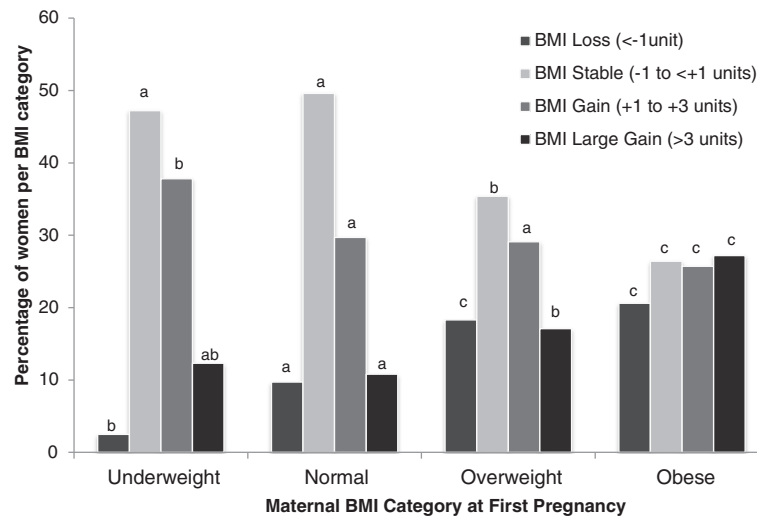

This study demonstrates that weight change during the inter-pregnancy interval is strongly associated with the risk of experiencing a range of pregnancy complications in the second pregnancy. This was true for women experiencing particular complications for the first time and for all women irrespective of their previous first pregnancy history. The data herein for women encountering a complication for the first time in the second pregnancy

Odds ratios (OR) and 95% confidence limits (CI) from logistic regression \*P < 0.05, \*\*P < 0.01 \*\*\*P < 0.001 relative to stable BMI reference group (OR = 1). Models adjusted for baseline BMI at first pregnancy, height and inter-delivery interval, and maternal age, year of delivery and smoking status, gestational age and baby gender at second pregnancy. Where appropriate, variables were additionally adjusted for the co-occurrence of pre-eclampsia or gestational hypertension. For each individual endpoint women experiencing the complication in the first pregnancy were excluded. For the < -1, -1 to 1, 1 to 3 and ≥3 BMI change categories the distribution of the study population was 9, 50, 30 and 11% for women with a first pregnancy BMI of less than 25 (a) and 19, 33, 28 and 20% for women with a first pregnancy BMI of more than 25 (b). † Refers to BMI loss between pregnancies of more than 1 unit. \*Significance of trend for complication frequency rate from the Cochran –Armitage test and for odds ratios from calculation of overall Chi square value. SGA, Small for gestational age; LGA, Large for gestational age. Birth and placental weight categories based on gender and parity specific centile charts for Scotland [26,27].

**Figure 1** Percentage of women who were weight stable or who lost or gained weight between pregnancies in relation to maternal BMI category at first pregnancy. Where superscript letters differ within inter-pregnancy weight change categories,  $P < 0.01$ .

can be directly compared with the previous ten-fold larger population based study of Villamor & Cnattingius [15]. For women who gained 3 or more BMI units, this comparison reveals a striking similarity between studies in the adjusted odds ratios for major pregnancy complications including pre-eclampsia (1.85 vs 1.78), gestational hypertension (1.82 vs 1.76), and LGA (1.70 vs 1.87), and a comparable OR for emergency caesarean delivery (present study) compared with all caesareans combined (1.78 vs 1.32). In contrast to previous studies [15,20], inter-pregnancy weight change was not associated with the risk of stillbirth but our inability to detect a relationship may partly be due to a combination of the generally low incidence rate of this complication and the considerably smaller size of our study population. In the present study, inter-pregnancy weight loss was associated with a 46% higher risk of spontaneous preterm delivery while a large BMI gain was modestly protective (35% lower risk). Both the direction and magnitude of these effects were very similar to those reported previously [22], albeit examining BMI changes in a different way and in a large study population of more than 200,000 women. In the latter study which used self-reported weight and height data, moving from a normal to an underweight BMI classification between pregnancies was associated with a 50% higher risk of spontaneous preterm delivery while moving from normal to overweight or obese categories was associated with a 20% lower risk of an early birth in both cases. In addition to confirming the general robustness of these previous observations, herein for the first time we demonstrate that inter-pregnancy weight loss is associated with a 65% higher risk of an SGA birth. Although not directly comparable, weight loss before pregnancy, calculated as an annual average between 20 years

of age and start of pregnancy approximately 9 years later, has recently been shown to increase the risk of an SGA delivery by 76% [28].

We additionally examined whether the above relationships between inter-pregnancy weight change and the risk of adverse pregnancy outcomes were dependent on a women's baseline BMI at the first pregnancy. In general the risks associated with weight gain (namely gestational hypertension, caesarean delivery and LGA birth) were higher in women who had a healthy BMI (<25) during the first pregnancy than for overweight women, emphasizing that individuals do not necessarily have to become obese *per se* to increase their risk of adverse outcome at the second pregnancy. The exception was the risk of pre-eclampsia which was three-fold higher in women who were overweight at baseline but not different from the weight stable reference group in women who had a healthy weight at this time. This is in sharp contrast to previous data indicating that the effect of inter-pregnancy BMI change on pre-eclampsia was independent of baseline BMI at the first pregnancy [15]. As the approach to the data analysis was identical the reason underlying this discrepancy is unknown but may relate to subtle differences in the diagnosis and hence classification of pre-eclampsia between data bases, or to the relatively higher percentage of women in our population with a large inter-pregnancy BMI gain (3% more in both initially healthy and overweight categories). With respect to those complications associated with inter-pregnancy weight loss, the risk of a SGA birth was independent of BMI at baseline, suggesting that any downward movement between BMI categories is likely to increase the risk of this complication. In contrast the risk of spontaneous preterm delivery following inter-pregnancy weight loss was apparent only in

women who had a healthy BMI at baseline. The lack of effect in women who were initially overweight (BMI >25) is in complete agreement with previous work where moving from obese to overweight or normal, and overweight to normal BMI categories did not alter the risk of spontaneous preterm delivery relative to the BMI stable normal reference group [22].

The public health implications of these findings are considerable. The natural assumption is that women who were obese at the start of the first pregnancy are more vulnerable to excessive weight gain during that pregnancy and in the subsequent postpartum period. While this was true for approximately 25% of our study population, a considerable number of initially overweight and obese women (18 and 20%, respectively) lost weight between pregnancies thus theoretically negating the risk of many of the maternal and perinatal complications associated with weight gain but increasing their risk of a SGA birth. In partial support a recent retrospective study involving more than 700,000 women has specifically shown that gestational weight loss protects against pre-eclampsia and emergency caesarean section but increases the risk of prematurity and SGA in all but the most severely obese women [29]. We have no information on the underlying causes of weight change in either direction in the present study but likely candidates not controlled for in the analysis presented here include inappropriate gestational weight change, diet, physical activity, breastfeeding and socio-economic status. Further it is possible that the use of customized birth weight centiles (based on maternal height and weight at booking) to define birth weight extremes may subtly alter the reported relationships. While the consequences of large inter-pregnancy weight gains are arguably more serious for a women's long term health our results suggest that a degree of caution is required if health professionals promote weight loss at this time, particularly as the effectiveness of dietary and lifestyle intervention strategies aimed at improving pregnancy outcome among both normal and obese women remain largely unproven [30,31].

Together the present and previous studies linking inter-pregnancy BMI change in both directions with a range of contrasting pregnancy complications implies a causal relationship, although we cannot determine whether it is weight change or the behaviours leading to it that confer extra risk. Nevertheless the present study further suggests that some of these relationships may be mediated in part by the placenta. Placental size, morphology, blood flow and nutrient transport functions primarily determine the growth trajectory of the fetus [32] and placental and fetal weight are strongly correlated [33]. Thus in light of the relationship between inter-pregnancy weight loss and SGA (1.76), and between weight gain and LGA ([15] and this study, OR 1.87 and 1.83, respectively), it is perhaps

unsurprising that our analysis also reveals that weight loss was associated with a similarly higher risk of low placental weight (OR 1.79), and weight gain with a greater risk of having a large placenta (OR 1.76). The implication is that these changes in maternal nutritional status between successive pregnancies impact maternal nutrient reserves at the start of the second pregnancy and hence the placental growth trajectory. Alterations in placental growth may in turn be on the causative pathway to some of the pregnancy complications studied herein. In partial support, studies in a highly controlled sheep model demonstrate that placental weight is profoundly influenced by BMI at conception (irrespective of subsequent gestational intake) and is closely associated with birth weight at delivery [34]. Moreover in term infants, placental weight has recently been shown to be an important intermediary between maternal conditions of overnutrition (namely pre-pregnancy obesity, excessive gestational weight gain and gestational diabetes mellitus) and increased birth weight [35].

A considerable strength of our study was that weight and height were measured at the first clinic appointment on both occasions and weight was adjusted to a standard gestational age for all maternities. This was a close approximation of pre-pregnancy BMI as it was recorded by clinically trained staff thereby negating recall bias. Moreover the data for the maternal weight corrections was originally derived from women with singleton live births between 32 and 42 weeks gestation from the same geographical area [24], and while arguably sub-optimal for women with stillbirth or post-term delivery is considerably better than no adjustment. Both maternities were at a single hospital and a number of known important confounders were measured and the analyses adjusted accordingly. A further strength is the uniform criteria used in the AMND to record pregnancy complications. On the other hand the study population after exclusions for missing data was relatively small and of low ethnic diversity. Moreover the low event rate for rarer complications such as stillbirth may have limited the power to detect all potential effects. Nevertheless the missing data do not appear to have introduced population bias as the proportion of women per initial BMI category at first pregnancy, the frequency of pregnancy complications in relation to first pregnancy BMI, and the relationship between inter-pregnancy BMI change and the primary incidence of specific pregnancy complications is commensurate with previous publications by other groups using other data sources [5-9,15-22]. Moreover the data was collected over a time range where changes in obstetrical practice might have been expected (eg. criteria for caesarean section) but this potential bias should have been minimized by including year of delivery in the adjusted model. Although the inter-delivery interval was similar between baseline BMI categories, it is acknowledged that the availability of this parameter in years rather than months is not

ideal and may have limited the accuracy of adjusting for this parameter in the model.

## Conclusions

In conclusion, inter-pregnancy weight change in either direction variously increases the risk of a number of contrasting pregnancy complications, including extremes of placental weight.

## Consent

This was a retrospective cohort study using routinely collected and fully anonymised data. As such individual patient consent cannot be obtained but a routine opt out clause is applicable at the time of antenatal booking as with all NHS clinical data.

**Cite this article as:** Wallace *et al.*: Inter-pregnancy weight change impacts placental weight and is associated with the risk of adverse pregnancy outcomes in the second pregnancy. *BMC Pregnancy and Childbirth* 2014 **14**:40.

**Submit your next manuscript to BioMed Central and take full advantage of:**

- Convenient online submission
- Thorough peer review
- No space constraints or color figure charges
- Immediate publication on acceptance
- Inclusion in PubMed, CAS, Scopus and Google Scholar
- Research which is freely available for redistribution

Submit your manuscript at
