The prevalence of severe maternal morbidity and near miss and associated factors in Sergipe, Northeast Brazil

Larissa Paes Leme Galvão, Fabiano Alvim-Pereira, Caio Menezes Machado de Mendonça, Filipe Emanuel Fonseca Menezes, Kaique Andre do Nascimento Góis, Ruy Farias Ribeiro Jr and Ricardo Queiroz Gurgel*

Abstract

Background: The investigation of severe maternal morbidity (SAMM) and maternal near miss (NM) and associated risk factors is important for the global reduction of maternal mortality. This study investigated the prevalence of SAMM and NM cases and the associated risk factors in two reference maternity hospitals in a capital city in Northeast-Brazil.

Methods: A cross-sectional study with a nested case-control component was conducted from June-2011 to May-2012. Case identification was prospective and data collection was performed according to WHO criteria and definitions. *Odds ratio* with confidence intervals and multivariate analysis were used whenever possible.

Results: There were 16,243 deliveries, 1,102 SAMM cases, 77 NM cases and 17 maternal deaths. The maternal NM outcome ratio was 5.8 cases/1,000 live births (LB); the total prevalence of SAMM + NM was 72.6 cases/1,000 LB, the maternal near miss: mortality ratio was 4.5cases/1 maternal death (18% of mortality index). Management-based criteria were the most common events for NM (87.1%) and hypertensive disorders for SAMM (67.5%). Higher age, previous abortion and caesarean delivery, the non-adhesion to antenatal care, current caesarean delivery and bad perinatal results were associated with SAMM/NM. In the multivariate analysis, patient's status, previous caesarian and abortion and level of consciousness were significant when analyzed together.

Conclusions: SAMM and NM situations were prevalent in the studied population and some risk factors seem to be associated with the event, particularly previous gestational antecedents. Protocols based on SAMM/NM situations can save lives and decrease maternal mortality.

Keywords: Severe maternal morbidity, Maternal deaths, Severe acute obstetric morbidity, Deliveries, Epidemiology, Maternal near miss

Background

Worldwide, approximately 800 women die every day from preventable causes related to pregnancy and delivery [1]. An additional ten million experience some kind of complication and a further three million neonatal deaths occur every year globally [2,3]. Most of these situations are preventable and 99% of maternal deaths occur in developing countries [1]. The maternal mortality ratio in Brazil is about 60.1/100,000 live births (LB) and a total of

1,719 deaths were estimated to have occurred in 2010. The main causes of maternal deaths this year were: hypertension (21.1%), hemorrhage (11.9%), complications of labor (9.6%), sepsis (8.6%), abortion (6.5%) and HIV and infectious disease (5%) [4]. Maternal deaths occur asymmetrically and vary according to the region in country and its state of development.

In most places, the study of maternal mortality has become increasingly difficult for several reasons, especially due to its rare occurrence. It is therefore very difficult to do population studies that aim to understand why these women die nowadays [5].

In 2009, the WHO established a set of criteria for SAMM and for NM in order to standardize data and calculate indicators for comparing different settings and identify cases of interest [6]. Severe acute maternal morbidity (SAMM) and maternal near miss (NM) are events involved in the biological *continuum* that goes from the normal expected healthy situation of a pregnancy to maternal death [7]. NM events are used to study situations where women survived, but nearly died due to a complication during pregnancy, delivery and postpartum and help to reduce maternal mortality by improving maternal health [8,9]. Despite these cases have several aspects in common with women who died (especially the same risk factors), fortunately these events are at least three times more frequent than maternal deaths. SAMM is a condition more broadly defined; the cases are less serious and represent a situation that precedes the NM situations in severity (Table four, [6]). NM situations are classified according to Table three in Say, Souza and Patinson paper [6], are more specific and often represent the stage that immediately precedes maternal death [6].

A systematic review, including 82 studies from 46 countries, demonstrated that the prevalence ranged from 0.04% to 14.98% [10]. Other similar studies found NM incidence ratios of 3.4 cases/1,000 deliveries and 18 cases/1,000 deliveries [11]. A recent Brazilian multicenter study, which adopted the new SAMM and NM classification from the WHO (2009), analyzed 27 reference maternity hospitals in one year and found 116.3 cases/1,000LB [12].

Brazil is a country with large territorial and economic disparities, making it difficult to accurately estimate the current SAMM/NM situation. The majority of the studies are based on populations from large urban areas and this is not representative of the general population. What happens outside of these centers, especially in the poorest areas, also contributes to the national situation. This study aims to determine the prevalence of SAMM and NM events, to describe the associated risk factors and calculate the indicators recommended by the WHO in the two tertiary public services located in Aracaju, State Capital of Sergipe, in Northeast Brazil.

Methods

A cross-sectional study with a nested case-control component was conducted to identify pregnant women who were at risk of SAMM and NM in the two reference maternity hospitals of Sergipe state, Northeast-Brazil, between June 2011 and May 2012. Case identification was prospective and data collection was performed concomitantly. The population studied is of a low socioeconomic level and the vast majority depend on the public health system. The two maternity hospitals used are the only reference maternity hospitals for the entire state: Santa Isabel Hospital and Nossa Senhora de Lourdes Maternity. The

first institution is responsible for 800 deliveries per month, is the reference maternity hospital for low and medium obstetric risk and has the only intensive care unit for obstetric patients in the state. The second is the high risk maternity hospital for the state (350 deliveries per month), and hosts reference services and specialists from other clinical and surgical areas related to obstetric conditions. Both institutions have teams of obstetricians, anesthesiologists and neonatologists available all the time and are equipped with a blood bank, surgical theaters and a neonatal intensive care unit. These two institutions serve a population of approximately two million people and include the entire population of the state and some regions from neighboring states [13].

In this study, we included all admitted patients that fulfilled the current criteria for SAMM and for NM according to the WHO-Working Group on Maternal Mortality and Morbidity [6]. The first requirement was to be a pregnant woman or to be within 42 days of puerperium, irrespective of the duration and pregnancy condition. Patients were included in the study only once, even if they were admitted on more than one occasion, and were excluded in the case of maternal death.

Three groups were selected according to the definition criteria and defined as: SAMM group, NM group and the control group [6]. This last group was selected from the same hospital, on the same day and with a ratio of two control subjects to one near miss subject. When a case was identified, all patients who were eligible to be controls (admitted on the same day) were listed and numbered and two numbers were selected at random from a covered box. Using such a strategy, bias selection was avoided as each eligible control had the same chance to be selected. The exclusion condition for controls was not having any eligible criteria for SAMM or NM or if they refused to participate.

Every 48 hours, the PI (responsible obstetrician) undertook an active search of cases in both hospitals to identify eligible patients. On the same day, after obtaining written consent from patients, trained medical students conducted the interviews with the patients and reviewed medical records. A pre-coded questionnaire with 59 questions was developed specifically for this study, containing information on sociodemographic profile, prenatal data, clinic and admission conditions, parity, previous pregnancy data, type of delivery, caesarean indications, complications during and after the delivery and perinatal results. Some standardized ratios were calculated, according to the current established definitions by WHO in 2009 [6]. Severe acute maternal morbidity ratio (SAMM-IR) and the overall prevalence were also calculated.

Data was entered in to a computer database using Microsoft Excel 2007. The statistical analysis was performed using SPSS (SPSS Inc., Chicago, IL, USA, version

16.0) for Windows and was double-checked before analysis; $P < 0.05$ was considered significant. Categorical variables were expressed as frequency and percentage and were tested using an exact Fisher test for 2x2 tables or a chi-square test for larger tables. For continuous variables, after testing normality with a Shapiro-Wilk test we used a student's t test for the normal and a U-Mann-Whitney for the non-normal variables. An *Odds Ratio* was used when NM and control values differed. Binary logistic regression multivariate analysis was used as a backward method, NM experience as the dependent variable. Independent variables were included when the p -value < 0.150 and represented at least 80% of the sample in each group. Any variables that did not reach the above conditions were included in the model. The confidence interval (CI) was 95% and a p -value of < 0.05 was considered statistically significant. The number of valid cases is indicated for each variable and missing data were excluded of from the analysis.

This study was approved by the Ethics Committee in Research of the Federal University of Sergipe, Brazil (Protocol number: 0184.0.107.000-11).

The authors used the STROBE statement and revised the paper accordingly.

Results

During the study period, there were 16,243 LB deliveries and we identified 1,102 SAMM cases, 77 NM and 17 MD. In order to compare the 77 NM cases, we randomly selected 151 controls. There were 94 women with a severe maternal outcome ratio (SMOR) (77NM + 17MD), with a ratio of 5.8 cases/1,000 LB. The maternal NM incidence ratio was 4.7 cases/1,000 LB and the SAMM incidence ratio was 67.8 cases/1,000 LB. The total prevalence (SAMM + NM) was 72.6 cases/1,000 LB (7.3%). The maternal near miss: mortality ratio was 4.5:1, the mortality index was 18% and the mortality ratio for the studied population was 104.6 cases/100,000 LB [Table 1].

The main conditions diagnosed in SAMM cases were: 67.5% with hypertensive disorders, 61.7% with severe management indicators, 15.4% with hemorrhagic disorders and 8.5% with other systemic disorders. For the NM cases, the main criteria were: 87.1% management-based criteria, 41.4% clinical criteria and 21.4% laboratory-based criteria. The sum was higher than 100% because frequently patients met more than one eligible criterion [Table 2].

While 56.9% patients meeting SAMM criteria and 53% meeting NM criteria were referred to the two reference hospitals by other health services; 58% of the controls came from their own residences ($p = 0.001$). Conditions diagnosing SAMM/NM were associated with higher age ($p = 0.018$), earlier gestational age at admission ($p = 0.016$), lack of antenatal care ($p = 0.013$), previous abortion and caesarean section ($p = 0.001$ for both), higher rates of

Table 1 Indicators of maternal morbidity and mortality for the population in the referral maternity wards of Sergipe

Coefficients	Ratios
Women with SMOR	5.8 cases/1000LB
NM incidence ratio	4.7 cases/1000LB
SAMM incidence ratio	67.8 cases/1000LB
Total prevalence (SAMM + NM)	72.6 cases/1000LB (7.3%)
Maternal near miss: mortality ratio	4.5 cases/1000LB
Mortality index	18%
Mortality ratio for the population	104.6 cases/1000LB

SMOR: severe maternal outcome ratio; LB: liveborn infants (16,243LB);
 NM: maternal near miss; SAMM: severe acute maternal morbidity.

current caesarean section ($p = 0.001$), unconscious state on admission ($p = 0.001$), and lower birth weight babies and newborn perinatal period with an unfavorable prognosis ($p = 0.001$ for both). SAMM cases had higher mean for systolic and diastolic blood pressure ($p = 0.001$ for both), [Tables 3 and 4].

When NM cases and controls were compared, a previous history of abortion [OR = 2.7 (CI = 1.4-5.4)] and caesarean section [OR = 1.9 (CI = 1.0-3.6)], higher rates of caesarean section [OR = 2.4 (CI = 1.1-4.9)] and being unconscious on admission more often [OR = 15.2 (CI = 4.3-54.2)] were notable differences between the two groups [Table 5]. Perinatal unfavorable prognosis, through the destination of the LB (ICU/death vs. with the mother) [OR = 8.1 (CI = 3.7-17.7)] was statistically significant.

In regard to the number of the eligible criteria per case, the univariate analysis demonstrated that 74.5% were eligible for more than one SAMM or NM criterion. During the study period there were 17 MD and the main causes were: hemorrhage (41.2%), hypertensive disorders (17.5%), embolism (11.8%), abortion (11.8%), baseline diseases complicated by pregnancy (11.8%) and pelvic infection (5.9%).

Table 2 The main diagnosed conditions for SAMM/NM cases in the referral maternity wards in Sergipe

Criteria	SAMM (n = 1102)		NM (n = 77)	
	n	%	n	%
Haemorrhagic disorders	152	15.4	-	-
Hypertensive disorders	666	67.5	-	-
Other systemic disorders	84	8.5	-	-
Severe management indicators	607	61.7	-	-
Clinical criteria	-	-	29	41.4
Laboratory-based criteria	-	-	15	21.4
Management-based criteria	-	-	61	87.1

The sum totaled more than 100% because the patients had were eligible for more than one SAMM/NM criterion. NM: maternal near miss; SAMM: severe acute maternal morbidity.

SAMM was hypertensive disorders. For NM, 87.1% were more frequently associated with management-based criteria and secondly with clinical criteria (21.4%). These numbers reinforce the specificity of the management problems-based criteria for NM in detecting patients with real severe obstetric [15]. Hypertension was the most frequent obstetric pathology and was the main cause of morbidity in the SAMM group. This was similar to the results reported for the rest of the country and to results from other developing countries [1,16].

However, inside the group of management-based criteria (the most common for NM) hemorrhage was the most frequent, highlighting the importance of this condition in the context of NM and the correlation with death. The maternal mortality ratio for the studied population was approximately 57% higher than the Brazilian national average (104.6/100,000 LB vs. 60.1/100,000 LB). The proportion of maternal near miss to maternal deaths

confirms other reports in the literature, which state that the condition is at least four times more frequent, which justify the study of NM [17]. The audit of these cases facilitates our understanding of the real demands of each health service, enabling us to improve the quality of obstetric care and to reduce the incidence of these preventable causes of death [6].

In terms of the sociodemographic variables that may be associated with SAMM and NM, the correlation between these events and higher age of the mother could be due to the fact that older women acquire chronic diseases throughout life. It may influence the gestational prognosis, increasing the chance of complications. Some studies suggest an association between SAMM/NM and marital status and education [15]. This was not observed in this study, possibly because this particular population is highly homogeneous: people live under similar socio-economic conditions, they are predominantly not white,

they are economically inactive and are dependent on public health services.

In addition, there was a significant association between SAMM/NM and patients who had a history of previous abortion, confirming findings from the literature [18]. Previous caesarean and current caesarean section were also statistically significant, but this occurred frequently even among the controls. In Brazil, the caesarean rate is considered a public health problem and this kind of delivery by itself increases the chances of repetition in the future [19,20].

Caesarean section, combined with an earlier gestational age on admission of the SAMM and NM cases, resulted in adverse perinatal outcomes and consequently more admissions to the intensive care unit and an increase in neonatal mortality ratios. In addition, an absence of prenatal attendance, and therefore lack of adequate monitoring, compounds a potentially life threatening condition by delaying an essential diagnosis and treatments that result in a good outcome for the pregnancy.

The univariate analysis indicated that the NM group presented with, in the majority of the cases (74.1%), more than one eligible criterion when compared to the SAMM group (25.6%). This shows how complex the management of NM cases can be, added to the severity of the criteria itself, suggesting a syndromic characteristic of NM and confirming the biological *continuum* theory where the lack of intervention may culminate in a real risk of death [7].

The results of the multivariate analysis indicate that a patient's previous obstetric history is valuable. Knowledge of a previous caesarian section is important because this kind of delivery is only justified in case of risk, which may reoccur during the patient's next pregnancy, despite the high rates of unjustified caesarean section in Brazil. Little is known about the associated risk between previous abortion and SAMM/NM (particularly hemorrhagic and infectious complications) [21]. However, this may be an important risk factor that is not commonly reported because some women tend to omit information on the practice of abortion, especially in countries where the legislation is restrictive [22,23]. Patients in the puerperium or that were submitted to curettage or postoperative had more SAMM/NM events because the event delivery/surgery itself may be the reason for the complication. The level of consciousness was associated with SAMM and NM because some patients exhibited high levels of severity since their hospital's admission.

There were a number of limitations to this study, such as the lack of electronic medical record storage making it difficult to have access to cases, limitations to the diagnostic and therapeutic resources in the services and the overcrowding of the maternity hospitals. We have exhaustively revised patients' records and made use of the available hospital database to minimize information loss. The lack of antenatal care, the lack of resources (e.g., no maternal intensive care unit available in the high risk maternity) were the main problems which led us to classify some patients as SAMM or NM, but the same criteria were used throughout the entire study without investigator interference.

SAMM and NM situations were prevalent in the studied population and some risk factors seem to be associated with the event, particularly previous gestational antecedents. The use of the WHO maternal near miss criteria was feasible in the Northeast of Brazil and provided useful information. Decreasing maternal mortality is more than ever a matter relevant to human rights and everyone has a part to play: government, human rights organizations, health service providers and civil society [24]. From an epidemiological point of view, it is necessary to enhance the coverage and the quality of antenatal care, to improve the infrastructure of maternity wards to

enable proper management of severe complications and to promote the work of multidisciplinary obstetric teams. Protocols based on adverse situations like NM, which identifies the exact point of failure prior to death, may allow us to recommend interventions that save lives.

Conclusions

The prevalence of SAMM and NM in the state of Sergipe was high, though within the ranges described in the literature. The mortality ratio for the population studied was also high, at least 40% higher than the Brazilian average. Hypertensive disorders were more commonly associated with morbidity, while hemorrhage was the main cause of mortality in this population. The only significant variable from the sociodemographic profile was higher age. Patients who have previously undergone a caesarean and/or an abortion should be noted and these should be considered obstetrical antecedents. The lack of regular antenatal care, high rates of caesareans and prematurity with adverse perinatal outcomes were also statistically significant. The existence of more than one criterion for NM eligibility demonstrates the complex management required for these patients and highlights the biological *continuum* for this situation.
